ABSTRACT
In the context of Component-based Programming, which addresses the implementation stage of a component-based software engineering development process, this paper describes a specification and an operational integration of an inheritance system into a self-contained new component-based programming language named COMPO. Our proposal completes and extends related works by making it possible to apply inheritance to the full description of components, i.e. both to structural (description of provisions and requirements, of component architecture) and behavioral (full implementations of services) parts in component descriptions. Inheritance in COMPO is designed to be used in conjunction with composition to maximize reuse capabilities and expressive power. COMPO implementation proposes a clear operational solution for inheritance and for achieving and testing substitutions.

1. INTRODUCTION
Component-based software is made of off-the-shelf components, connected together into various kinds of architectures. In this domain, several languages, using the component concept as a first class entity in organizing software, have been and are currently designed and prototyped, but some categories have emerged. Architecture Description Languages (ADLs) for models like Fractal [7] or SOFA [18] allow for business-oriented and implementation-independent components and architectures descriptions. Component-Based-Programming Languages (CBPLs) like ACOEL [22], ArchJava [1], CLIC [5], ComponentJ [21], Bichon [27], CompJava [19] or SCL [10, 9] address the implementation stage of a component-based software engineering development process; they allow developers to express full descriptions of executable components.

To create off-the-shelf components, reuse is or should be essential. Reuse can be considered from different point-of-view. Composition is a way to reuse a component by integrating it, as it is, into an engulfing component or into an application, and by invoking its services. Another way to reuse is to create a new component by stating how it differs from an existing base one, instead of creating it entirely from scratch. This is sometimes depicted as “differential description” and frequently achieved via inheritance systems. Inheritance has proved to be one major cornerstone of software reuse, first for the ability it gives developers to organize their ideas on the base of an incremental concept classification (a list is a kind of collection, such architecture is a kind of visitor, ...) which is itself one key of human abstraction power and second for the calculus model that makes it possible to not only reuse but adapt software, by executing an inherited code in a new context (the receiver environment).

Many of the above quoted component-oriented languages somehow propose inheritance mechanisms or inheritance-like[15] (see related work section) but they have various limitations (limitation to the architecture description side, limitation to the implementation side which is frequently not achieved with component-based languages, limitation to some part of components descriptions, etc). More generally, the question of the interest of inheritance-based reuse in the component-based software engineering context is still opened and its how-to remains to be explicit.

This paper aims at contributing to that question by showing the interest of a specification and an operational integration of a full inheritance system, in the context of a component-based programming languages, that supports reuse of components’ structure and behavior. By “structure”, we mean descriptions of interfaces, ports and internal architectural; and by “behavior”, we mean implementations of services that make them executable. Our language, COMPO, ranges in this category and proposes components as runtime entities, instances of descriptors. We introduce an inheritance link between descriptors on which we base...
an operational system to reuse, i.e., to inherit, extend
and specialize descriptions. Descriptors are texts describ-
ing components’ structure and behavior. Listings 1 and 2
are examples of component descriptors in COMPO.

We address the specific questions of stating what, among
port declarations, composition architectures and services
definitions, can be inherited, extended or specialized, and
how. We notably discuss the rationale and interest of en-
abling requirements extension or specialization: we will con-
cider various solutions, but will develop an answer to that
question which goes in the direction of enabling covariant
specialization, because it corresponds to the way human nat-
urally think about concept classification [8] and it promotes
expressive power. Our solution will thus propose simple sup-
port to help programmers achieve correct substitutions.

An alternative for reuse in the component-based software
development context is to use sole composition (see [20, 27]
and [26] for a good survey) and message redirection (or for-
warding; or delegation\(^1\)); it has the advantage of not in-
troducing any additional mechanism. Our opinion is that
composition and inheritance are complementary and that
their combination is significantly more efficient especially
when structural reuse is to be considered. The above alter-
native will be further discussed in the related work section,
where we show some examples in which sole composition
usage leads to code being too complex and reuse being dif-
ficult. Inheritance in COMPO is thus designed to be used
in conjunction with composition to maximize software reuse
capabilities and language expressive power.

The paper is organized as follows. Section 2 proposes
an overview of COMPO essential constructions and syntax.
Section 3 is a step-by-step (services declarations, require-
ments declarations, internal architecture description) discus-
sion and presentation of our inheritance system specification
illustrated with various examples. Section 4 gives some ba-
sic clues on the COMPO’s implementation. Before concluding
and discussing the future work, we present in Section 5 the
related works.

2. A SUPPORT COMPONENT-BASED
PROGRAMMING LANGUAGE

Our proposition for inheritance is demonstrated and val-
ified via its integration into a component-based language
named COMPO. Although the language itself is not the sub-
ject of this paper, it is needed that we give an overview of
its main constructs and syntax. COMPO is an ongoing work
that aims at defining in an unified context (1) a component-
based architecture description and modeling language that
includes all standard component architectures concepts and
constructs (e.g., component, ports, interfaces, connections,
constraints, etc) and (2) a component-based programming
language making it possible to write executable applications,
in which all the above concepts and constructs are available
as first-class entities. This language overall goal is to allow
standard applications or architecture verification and trans-
formations applications to be written in the same language,
via an integrated meta-level. COMPO is here used for our op-

\(^1\)Although delegation in prototype-based language is differ-
ent, in fact an object-level inheritance mechanisms[3], we
will use for message redirection the terms "message delega-
tion" and corollary "delegation connector" and "service invo-
cation delegation" with semantics as specified in UML [16].

erational study on inheritance because, as far as we know,
there exists no other language in which component architec-
tures and services can be written in the same context and us-
ing the same high-level constructs for component-based de-
velopment. Many component-based architecture are for ex-
ample translated into Java template code and implemented
in a world where concepts such as ports do not have a first-
class status.

From a concrete point of view, within a component de-
scription (see e.g., listing 1), the provides, requires, in-
ternally requires and architecture sections are related
to components modeling and architecture description. The
service section is related to services programming; this sec-
tion can be omitted if the architecture is to be generated into
another language.

2.1 Component descriptors.

COMPO applies the descriptor/instance dichotomy where components are instances of descriptors. A component
descriptor is a text describing the structure (ports decla-
rations and architecture description) and the behavior (set
of services definition) of its instances.

```
component descriptor FrontEnd {
  provides {
    default : { run(); isListening(); }
  }
  requires {
    backEnd : { handleRequest(r) }
  }
  internally requires {
    rR <: RequestReceiver;
    s : TaskScheduler;
  }
  architecture {
    delegate default to rR.default;
    connect s to (TaskScheduler new).default;
    connect rR.schedular to s0.schedule;
    delegate rR.handler to backEnd;
  }
  service isListening() {
    " rR isRunning.
  }
}
```

Listing 1: The FrontEnd descriptor
i.e. requirements can be satisfied only with anonymous references to components, i.e. TaskScheduler new). (4) the internal architecture of a FrontEnd, (5) the public services of a FrontEnd, only one (isListening) being shown. Concepts and syntax used in this example are detailed in the following sub-sections also using the description of an HTTP Server (see listing 2) which uses a FrontEnd.

2.2 Ports

In COMPO, a port is a connection point (components are connected through their ports) and a communication point (services invocations are transmitted via ports). A port is defined by a an owner component, a name, a list of service signatures, a visibility (external or internal) and a role (provided or required).

The role of a port is either required or provided with a standard semantics: a provided (resp. required) port lists, the signature of services offered (resp. required) by a component.

The list of services signatures associated to a provided port can be given:

• as an explicit list (we call such a list an anonymous interface) (the default port declaration in Listing 1 is an example).

• via a named interface (see Section 3.3 ),

The list of signature associated to a required port can be given as an explicit list or via a named interface, as above, or via a component descriptor name (e.g. cd); in this case, the list is the list of signatures of services associated to cd’s default provided port (the sched port declaration in Listing 1 is an example).

The visibility of a port is either internal or external (the default is “external”).

• An external port ep of a c component is visible and can be used by an architect to interconnect c into an englobing composition architecture. For example, the external required port backEnd of an instance of FrontEnd can be connected to the external provided port default of an instance of BackEnd as shown in listing 2 and in figure 1 (we are developing both textual and graphical component definition interfaces).

Each component has a default external provided port (named default) listing signatures of public services of its owner component, and has a default and unique internal provided port, named self (for obvious historical reasons), listing signatures of all services of its owner component and allowing any of its services to invoke another one.

• An internal port ip of a c component is a support for accessing c’s internal composition architecture, ip and the component connected to it (that we call an internal component of c) are invisible from the outside of c. In Listing 2, it is shown how the two internal required ports of a HTTPServer are connected to its two internal components: a FrontEnd and a BackEnd, allowing it to invoke their services (e.g. fe isListening in service status).

• The list of external ports (provided and required) define the external contract of a component.

2.3 Connections

A connection establishes a dual referencing between two ports, making it possible to determine whether a port is connected or not and, if true, to which other port it is connected. When we sometimes write, in a somehow misleading but admitted way, that two components are connected, it is meant that one port of the former is connected to one port of the later.

• A regular connection is between a required and a provided port. The syntax for connections is: (connect | delegate) <port> to <port>, where <port> is any expression returning a port. An example of an expression establishing a regular connection is: connect s to (TaskScheduler new).default; (see. Listing 1).

• A delegation connection is between two ports having the same role and is used to delegate a service invocation from an external to an internal via the composite (provided to provided), or from an internal to an external via a composite (required to required). An example of a “provided to provided” delegation connection is delegate default to rR0.default; in Listing 1).

2.4 Internal architectures

An internal architecture of a component is the set of its internal components (components connected to its internal required ports) together with their inter-connections. A component having internal component is as usual called a composite. Initialization (i.e. instantiation and connection) of internal components of a composite c is performed during c’s instantiation if described in the c’s descriptor architecture section.

For example, the internal ports and architecture sections of descriptor HTTPServer define the following internal architecture for its instances.

• The internal required port fE is connected to a FrontEnd.

• The internal required port be is connected to a BackEnd. Note that: be c:: BackEnd in the port section is a shortcut to avoid writing the following instruction in the architecture section: connect be to (Backend new).default).

Figure 1: HTTPServer, the diagram shows a logical representation of an instance of the HTTPServer descriptor presented in Listing 2, after it has been created and initialized.
• The internal required port name is connected to a String. String is a predefined component descriptor the role of which is to interface all basic types of the hosting language so that their elements can be used as standard components. Predefined descriptors expose a single provided port named default through which procedures or methods of basic types can be called in the form of a service invocation via the COMPO interpreter or virtual machine.

• a delegation connection is created between the provided port default and the default port of the frontEnd.

• a regular connection is created between the required port backEnd of the component connected to the fE internal required port and the port default of the component connected to the bE internal required port: connect fE.backEnd to bE.default.

This connection is a good example of a situation in which architecture design requires that a reference be made to a component which is not yet created. Here we need to say that we want to connect the port backEnd of the component that will be connected to port fE. The @ operator makes it possible, for any port p to reference the component that will later on be connected to p and subsequently to specify an architecture before descriptors are instantiated.

```
component descriptor HTTPServer {
  provides {
    default : { run(); status() }
  }
  internally requires {
    fE : FrontEnd;
    bE <: BackEnd;
    name <: String;
  }
  architecture {
    connect fE to (FrontEnd new).default;
    delegate default to fE.default;
    connect fE.backEnd to bE.default;
  }
  service status () {
    fE.isListening
    ifTrue: [ "name printString + 'is running' ]
    ifFalse: [ "name printString + 'is stopped' ].
  }
}
```

Listing 2: The HTTPServer descriptor.

### 2.5 Services & Service invocations

Services implement the behavior of components. A service may have parameters and may return a value.

Components communicate by service invocations made through required ports. A service invocation consists of a port name, a selector (the name of the requested service) and optional arguments. fE.isListening is an example of a service invocation made through the fE.port in the context of the status() service of component HTTPServer. When a required port receives an invocation it transmits it to the port it is connected to. The receiving port then transfer the invocation to its owner component which is responsible for handling it (either executing a corresponding service or delegating the invocation via a delegation connection, full detail on this can be found in [10]).

### 3. RATIONALITY AND RULES TO REUSE DESCRIPTIONS WITH INHERITANCE

This section presents the rationale and the operational description of our descriptor-level inheritance embedded in our CBPL. Ports declarations, internal architecture definitions and initializations, services definitions, and more generally all pieces of code specified at the descriptor level are subjects to inheritance, extension and redifinition.

For the sake of simplicity, we have limited our proposal to single inheritance relationship.

#### 3.1 Descriptors and basic inheritance

Any descriptor can be defined as a sub-descriptor of an existing descriptor (D). In such a case, D’s port declarations, internal architecture and service definitions are inherited. Every sub-descriptor has, by default, the super internal provided port. The port differs from regular provided ports in one small detail: services implementations demanded by service invocations sent to this port are looked up starting from the super-descriptor of the owning descriptor (not directly from the owning descriptor as it is in the case of regular provided ports).

Listing 3 show the ControlableFrontEnd sub-descriptor that extends the FrontEnd descriptor (shown in Listing 1) with a new port named control. Ports declarations and internal architecture described in the FrontEnd descriptor are inherited by the ControlableFrontEnd descriptor, this is taken into account when creating an instance of the ControlableFrontEnd descriptor whose structure will conform to what is described in the FrontEnd descriptor.

In Listing 4 we show an another sub-descriptor named RestartableFrontEnd which extends the ControlableFrontEnd descriptor with a new service. Services defined in the FrontEnd and ControlableFrontEnd descriptors are inherited by the RestartableFrontEnd descriptor. This is taken into account when instances of the RestartableFrontEnd descriptor are created and receive services invocations (lookup algorithm).

```
component descriptor ControlableFrontEnd extends ControlableFrontEnd {
  provides {
    control : { start(); isRunning(); stop() }
  }
  architecture {
    delegate control to rE.control;
  }
}
```

Listing 3: The ControlableFrontEnd descriptor. Extends the FrontEnd descriptor with a new provided port named control.

#### 3.2 Extension & specialization of services

To be able to inherit, extend and specialize the behavior defined by a component descriptor, a sub-descriptor can introduce new services and its instances can access and reuse services defined by its super-descriptor. This gives us ability to define behavior that’s specific to a particular sub-descriptor, i.e. achieve polymorphism of descriptors. A service can be redefined in a sub-descriptor and can reuse the one it specializes by using the super internal provided port.
Listing 4: The RestartableFrontEnd descriptor. Specializes the control port of ControlableFrontEnd descriptor and service isListening inherited from FrontEnd

Sending an invocation to super states that the service implementation should be looked for in the super-descriptor of the descriptor in which the current service in execution has been found. Listing 4 shows an example of specialization and extension of services, where the descriptor RestartableFrontEnd extends the descriptor ControlableFrontEnd with a new service restart() and specializes service isListening() defined in ControlableFrontEnd. super is used to access ControlableFrontEnd’s implementation of the isListening() service.

3.3 Extension & specialization of declarations of provided ports

The basic goal here is to be able to introduce a new provided port declaration and be able to specialize a declaration (i.e. a list of service signatures) of an inherited port. This capability leads to a higher expressive power. For example, sub-descriptors are able to export an internal behavior via newly added ports. Such an export does not break the encapsulation of the internal component, because it exports behavior which has already been public. Another use is definition of more viewpoints for a component, where each provided port represents a viewpoint on the component. Specialization of ports introduces more precise modeling possibilities for software architects. An example of extension and specialization of provided ports is illustrated in Listings 1, 3 and 4, where the ControlableFrontEnd descriptor extends original FrontEnd descriptor with a new port named control. The RestartableFrontEnd descriptor specializes the inherited port control with a new service signature.

The specialization of port roles makes sense only from the required role to the provided role. Indeed, this kind of role specialization can be performed simply by a delegation of a required port to a provided port of a component. Thus, there is no reason for allowing specialization of the roles of ports.

We extend a set of ports simply by introducing a new port in a sub-descriptor. A name of newly added port cannot clash with existing port names. In Listing 3 we extend the original FrontEnd descriptor with a new port named control in order to export control behavior offered by the internal component connected to the rB internal required port.

There are two scenarios how to specialize the list of service signatures of an inherited port: (1) a specialization by adding new service signatures to its list of service signatures (i.e. extending an anonymous inherited interface). The

RestartableFrontEnd example in Listing 4 shows the specialization of the control port defined by the ControlableFrontEnd super-descriptor. The specialization is used in order to provide the restart service defined by the descriptor RestartableFrontEnd. (2) a specialization using a named interface. In this case the set of service signatures defined in the named interface has to be a super-set of the set of service signatures used to describe the original port. A specialization of a port named portA looks like: provides { portA : Ispec }. In the super-descriptor, portA was declared by the statement: provides { portA : { ser1(); ser2(); } }. The Ispec interface was defined with the statement interface Ispec { ser1(); ser2(); ser3(); }. The named interface Ispec defines a set of service signatures, which is a super-set of a set representing the anonymous interface of the original portA therefore it can be used for the specialization.

3.4 Extension & specialization of declarations of external required ports

The usual practice with differential descriptions is incrementation. A colored circle is like a circle and, in addition, has a color. The reverse perspective saying that a circle is a colored circle without a color does not conform to the way people usually think. To have a color assigned is a requirement for a colored circle. To make requirements explicit is one characteristic of the component-based approach. In the object-oriented world, it is common to define an additional attribute in a subclass. It is however an issue to know whether it is allowed to define a new required port on a sub-descriptor. In fact it raises the same issue in both worlds: it possibly breaks child-parent substitutability, or more precisely, it may lead to incorrect substitutions as explained later on. For the sake of expressive power, we choose to enable declaration of new required ports in sub-descriptors. For the same reason we enable the covariant specialization of required ports in sub-descriptors. This prevent static checking of the correctness of substitutions and of course a different choice could be made in a language without calling into question the overall interest of the heritage in the component context. Without such capabilities, we would not be able to extend the Emailer descriptor shown in Figure 2 with a new required port semanticsChecker or specialize its required port syntaxChecker with a new required service signature grammarChecking().

For what concerns the substitutability issue, in OOPs, substitutability between sub-classes and super-classes is guaranteed. To be more precise, interface compatibility is guaranteed. Behavior compatibility is still not guaranteed,
the descriptor RandomRequestsQueue extends the RequestsQueue descriptor
NOTES: the descriptor QueueHTTPServer extends the HTTPServer descriptor (shown in Figure 1)
in
queue
stance
This is illustrated in Figure 3 and Listing 5, where an in-
ponents dependencies and can lead to unspecified behavior.
substitution principle [13]. These operations change com-
tem. In other words, adding new required ports (or specializ-
ing a required port in a sub-descriptor) violates the Liskov's
stance of such a sub-descriptor is used where an instance of
potentially non-substitutable sub-descriptor is possible. Addi-
required ports may became unsatisfied, when an in-
other words, adding new required ports (or specializing
required port in a sub-descriptor) violates the Liskov’s
ution is correct if when trying to substitute x (a A) by y (a
of pairs
Compat:
the instance is the internal component connected to the
instance is the internal component connected to the
example
shown in Figure 2; (2) constrain substitutions - define a rule
saying that an original component can be substituted by
a new one, only if the new one provides at least the same
and requires at most the same as the original one; (3) al-
allow additional requirements and delegate responsibility for
additional requirements satisfaction to the language users,
while providing verification support for substitutions. With
Compo all alternatives could have been implemented, but
since the language is oriented toward modeling flexibility, we
have experimented with the third alternative. We will thus
support covariant specialization if and when needed because
it corresponds to the way human naturally think differential
description [8]. Our inheritance mechanism does not ap-
ply any restrictions to implicitly guarantee substitutability.
Substitutions in Compo are under the developer’s control
and responsibility.
We are providing three support methods: (1) the new-
Compatible method to return a component compatible with
the super-descriptor of the component (the service is au-
tomatically created for each sub-descriptor which extends
its parent with additional requirements); (2) the reconnect
method (executed when a substitution is performed) to warn
users about unsatisfied additional requirements (by an ex-
ception) and (3) the isCompatibleWith method to help devel-
opers to check the validity of a substitution. For an example of
usage see Listing 5.

The first substitutions support comes in case when a sub-
derscriptor has an additional required port. Then our inheri-
tance system automatically generates a method called new-
Compatible: The method has a unique parameter, an array
of pairs port-component. The method is able to create an
instance, which is substitutable with instances of the super-
dercriptor. That is all additional requirements are satisfied
by connections to components given in the array argument.
The second support is the reconnect:to: method to
achieve substitutions safely. This method takes two argu-
ments, the first one is the name of an internal required port
referencing the component which should be replaced and the
second argument is the replacing component. The replacing
component should be mandatory created as an anonymous
reference (FrontEnd new), because, we do not allow an inter-

Figure 3: Dynamic substitution with a sub-
dercriptor having additional required port may lead to unsatisfied requirement in the architecture. Grayed parts of the figure illustrate inherited parts.
nal component be referenced outside of an owning composite (see second paragraph of 2.1) reconnect:to: checks for compatibility between the original and the new component descriptor, i.e. checks if the new component provides and requires at least the same as the original one and checks if all requirements will be satisfied after substitution. If all requirements of the new component are satisfied, the replacement is performed, otherwise an exception is thrown. reconnect:to: reconnects all ports of the original component to corresponding ports of the new component and connects the new component to the corresponding internal required port of the composite to reference the new component.

For components compatibility checking purposes we provide isCompatible method. The isCompatible method is able to compare the external contracts of compared components and answer by true if they are compatible and false otherwise. The method is useful for the reconnect:to: method, which warns users in the case of unsatisfied requirements.

```
component descriptor QueuedHTTPServer extends HTTPServer {
  internally requires {
    queue <: RequestsQueue
  }
  architecture {
    disconnect fE@.backEnd from bE@.default;
    connect fE@.backEnd to queue@.in;
    connect queue@.out to bE@.default;
  }
}
```

Listing 6: Specialization and extension of an internal architecture.

### 3.5 Extension & specialization of internal architectures

Internal architecture description and initialization is inherited by a sub-descriptor and it can be extended and specialized. When a large and complicated architecture needs to be reused, the language should support such a feature. Our motivation is based on general experience of building object-oriented application, where it is common that a class describes objects, which are composed of many objects communicating together. Such classes are often sub-classed. The sub-classes modify and extend original composition and communication system of their parent. This also applies in the component world and we can think of many situations in which a new architecture will be based on an existing one. As an example consider Figure 3 in which a QueuedHTTPServer is like a HTTPServer, but instead of having a direct connection between the fE (FrontEnd) and the bE (BackEnd), an adaptor, here a queue, is inserted in between fE and bE.

In COMPO, a sub-descriptor may extend a set of internal components by introducing a new internal required port. Usually this action implies extension and specialization of internal connections. These operations are illustrated in Figure 3, where the descriptor QueuedHTTPServer extends the descriptor HTTPServer with a new internal component named queue (described by RequestsQueue). And it specializes the inherited connections in order to assemble the queue component into the architecture of its super-descriptor. COMPO code of QueuedHTTPServer is given in Listing 6.

Specialization of an inherited internal component in a sub-descriptor can be achieved by modifying the interface description of the internal required port associated with the internal component. The descriptor of PriorityQueuedServer in Listing 6 specializes an inherited internal component queue by describing it with the PriorityRequestsQueue descriptor.

The specialization of an inherited internal connection can be achieved by the combination of statements having the following syntax: disconnect <port-name> from <port-name> and connect <port-name> to <port-name> (statements were explained in Section 2.5). Every time the disconnect statement is used, the removed connection has to be superseded by a new connection. The new connection does not have to be direct, i.e. there could be a middle component, but a connection string replacing the original connection has to be specified.

### 4. IMPLEMENTATION

The current implementation of COMPO is used as a laboratory for exploring new ideas and is built in [4] as an extension of the Scl [10, 9] implementation in the context of a global effort towards the development of efficient dynamic languages. We have chosen Smalltalk because we are a part of the effort to bring component concept into the Pharo environment. Descriptors and sub-descriptors are implemented as subclasses of the CompoComponent class. The CompoComponent class contains the mechanism to store necessary information about ports and associated interfaces, internal components and connections. The inheritance mechanism uses Smalltalk’s meta-model facilities to implement extension and specialization operations for both the structure and behavior of descriptors.

Readers can download a Pharo image of COMPO implementation here: http://www.lirmm.fr/~spacek/compo/

### 5. RELATED WORKS

In this section we give an overview of how inheritance is used in existing Component-based Programming Languages (CBPLs) and ADLs, and compare this with our proposal. We also compare our proposal based on a combination of inheritance and composition with inheritance-free proposal in which all reuse schemes are achieved using sole composition.

It is important to note, that none of these languages we have studied propose a complete specification of inheritance which concerns all main reuse aspects. Our knowledge about the behavior of their inheritance mechanism often had to be extracted from experiments conducted using these languages. The list of related works is not exhaustive; especially ADLs that do not support any form of descriptors inheritance are not included.
5.1 Inheritance in related CBPLs

Here, we compare how related CBPLs integrate inheritance aspects such as: the structure inheritance, the behavior inheritance and abilities to extend and specialize particular definitions in a component descriptor (i.e. ports, internal components and connections.) As related CBPLs we consider ACOEL [22], ArchJava [1], CLIC [5] and CompJava [19], because these languages combine implementation and architecture specification.

Structure inheritance is partially supported in all other languages. We say partially, because CompJava do not allow the reuse of internal components and connections specification. Ports declarations can be reused via component type definition. Except that they use a different terminology, the languages define component type as a set of port names including interface references and roles specification. And then a component type can be defined as an extension of an existing component type. Compo can do the same, a descriptor may extend another one and it inherits whole structure of the latter.

Behavior inheritance is fully supported only in CLIC and ArchJava languages. ACOEL model supports implementation inheritance by the extend statement, but a child cannot access any of the internals (implementation classes, methods) of a parent, except via the input ports of the parent, i.e. this.<portname> (composition-like approach). The advantage of this black-box approach is that it preserve encapsulation of parent components. We support white-box approach to be able to specialize services implementations which are not provided by a parent.

Ports specialization is not supported in ArchJava, because adding new provided methods to an existing port might cause ambiguities if these provided methods were required by a connected component, and provided by a different component. There would then be two components providing the same required method, breaking ArchJava’s connection rules. Adding required methods to an existing port would make the component class non-substitutable for the component superclass, because connections made to the superclass might not provide the subclass’s required methods. Required methods in a new port are also problematic, because the new port might not be connected at all. CompJava supports full specialization of provided and required ports, i.e. extending interfaces of inherited ports.

An interesting solution comes with ACOEL model, which uses ports parametrized by mixins [6]. During instantiation a mixin can be passed as an argument of a component constructor and a parametrized port is then “decorated” with new behavior (see Listing 7). CompJava’s ports are descriptions of communication and connection points. Therefore, they do not carry any implementation of behavior or its specialization.

Ports extension is well supported, i.e. except some limitations in CLIC and CompJava all models, including CompJava, may add new ports to descendants. CLIC model does not support additional provided port, because this model allows components to have only one provided port. The idea of a single provided port is based on the observation that developers do not know beforehand, which services will be specified by each required port of a client component. Therefore it is hard to split component functionality over multiple ports. We see this as a unnecessary limitation of modeling power.

On the other hand, in the CompJava, a component type may extend another component type and it inherits all ports.

</tr>
</tbody>
</table>

Listing 7: ACOEL mixins

It may extend the interface of inherited provided ports or may add provided ports. Extension of required ports is not allowed due to the substitutability policy of the CompJava model.

Architecture extension and specialization. ACOEL, ArchJava, CLIC and CompJava can extend the internal architecture. Specialization is supported only in CLIC and CompJava. ACOEL and ArchJava treat internal components as regular instance variables of classes and therefore there is no way to specialize inherited internal components. CompJava supports inheritance of component types only. Component types do not involve internal components and connections declarations, therefore architecture cannot be reused.

Substitutions. ACOEL, ArchJava and CompJava define sub-type relation as defined by Liskov [13]. In general, a component type is a sub-type of another one if it provides at least the same and requires at most the same. To ensure ACOEL use a type system checking. CompJava and ArchJava forbid additional requirements (in inherited types) and then they restrict substitutability by the sub-type relation.

In Table 1, we make a summary of this comparison.

Table 1: Comparative table of inheritance in selected CBPLs and in Fractal and SOFA models

5.2 Inheritance in related ADLs

Structure reuse is a primary inheritance property supported by ADLs [17], which operate mainly at design stage in the development process. They make it possible to design software using components and then convert them into a component framework written in OOPPLs or other programming languages (but not CBPLs). ADLs generally do not support behavior inheritance, because behavior of components is specified either in programming languages they are implemented in, or using some formalisms where there is no inheritance.

For example Fractal and its Fractal ADL allow to extend one component definition with another one, then a
Figure 4: The "lost of initial receiver" problem, when composition and invocations forwarding are used. The context pseudo variable self does not refer to the original receiver of service invocation when delegations are used. The m2() service of descriptor Child is never called

sub-definition can add or override elements. It also extends component type definition with contingency (optional or mandatory) and cardinality for each port. It is possible to add connections but impossible to specialize an inherited connection.

SOFA Component Definition Language (CDL) uses the frame term for component types. One frame can inherit from another frame and then port declarations are reused. To compose several frames, SOFA introduce architecture construct, where an architecture implements a frame and may inherits from another another architecture. In this way, internal components and connections are reused. Ports are specialized using interface redefinition i.e. by the following statement frame ComponentName inherits InheritedCompName changes InterfaceInstance1:: OriginalInterfaceType1 => NewInterfaceType1. Specialization of inherited connections is supported by the statement: newTiel, newTie2 replacing originalTie subsame subcomplInstName:intInstName to intInstName exempt: subcomplInstName:intInstName.

Other ADLs do not specify inheritance between descriptors, they usually use inheritance uniquely for creation of sub-interfaces. In UML, the component entity inherits from the structured class entity and therefore they can participate in generalization relationship in the same way as classes do.

5.3 Composition as a reuse mechanism

In ComponentJ [21] the authors state that all reuse schemes are achieved using sole composition. By nature, the composition concept allows only black-box reuse. Therefore it cannot be used when an internal architecture of a descriptor needs to be reused. For example the reuse of a descriptor's internal architecture shown in Figure 3 cannot be performed with composition.

Achieving behavioral inheritance by using composition and message forwarding raises various issues including the well known "lost of initial receiver" problem [12]. The context reference self (or this in some languages) does not refer to the original receiver of service invocation when forwarding is used. The problem and its solution are illustrated in Figure 4, where the m2() service of descriptor Child is never called.

ComponentJ proposal describes an operational solution to that problem. The solution is based on a connexion of the "self" port of the composed-component to the default provided port of the composite and on the service invocations forwarding from the composite to the composed-component (see the dashed arrow in the bottom of Figure 4).

The solution is operational but we argue that inheritance is preferred because it: (1) enables abstract description and conceptual description; (2) does not increases the complexity of the system and therefore preserve code maintainability of large systems, where hierarchical concept modeling is used; (3) copy the structure of an external contract of a super-descriptor (i.e. declaration of provided and required ports) automatically to sub-descriptors.

5.4 Resemblance as an alternative

In [15] an inheritance-like mechanism supporting component reuse and evolution is presented in context of ADL Darwin. The resemblance construct allows one component to be defined in terms of differences (adding, removing, modifying) with another, such that the base definition is not affected. The mechanism does not imply a subtype relationship between components in the way that inheritance usually does between classes [23], because ports, internals and connections can be added and removed. Our proposal also support the differential description process but the support is uniquely incremental. Removing existing declarations is forbidden 3, because such operation makes it difficult to understand how far differ two distant nodes in an inheritance tree.

6. CONCLUSIONS

In this paper, we have proposed an original descriptor-based inheritance system for a component-based programming language taking into account in the same context the architecture modeling and coding aspects of components. We have motivated and described concrete solutions for creating new component descriptors by extending and specializing existing ones and for extending or specializing all key primary aspects of component modeling and programming: ports declarations, composition (or connection) architectures, services declarations and definitions. These solutions are implemented and can be tested with our prototype (http://www.lirmm.fr/~spacek/compo/) implemented in Pharo Smalltalk [4].

Among the various possible specialization options for inheritance, we have applied in our context the covariant-oriented one, by allowing to add requirements on a sub-descriptor, that promotes expressive power and reuse. We have implemented supports to help programmer achieving substitutions. Other well-known approaches can of course be considered. Besides, we have not yet discussed the multiple-inheritance option. Inheritance in component-based development is useful for both "development-for-reuse" and "development-by-reuse". It helps, in combination with other composition techniques, in effortless production of new off-the-shelf components or new applications embedding complex components architectures.

There are various prospective for this work. The first one is to obviously to gain more experience on using inheritance in this context and to consider its use in designing Compo-

3except for connections, where a removed connection has to be mandatory replaced by a new connection
Compo
ture, to write model-driven verifications or transformations of component-based applications in Compo itself. We are applying it to constraint-based architecture verification, extending our earlier works [24, 25] towards constraint-components hierarchies.
